

What Types of Urban Greenspace are Better for Carbon Dioxide Sequestration?¹

Mark Hostetler and Francisco Escobedo²

Introduction

Meeting Florida House Bill 697 requirements to reduce Florida's carbon emissions will require a judicious look at how human-dominated landscapes are performing. It has been suggested that conserved urban greenspace could be used for carbon credit. But are all types of open spaces equal in terms of their ability to sequester carbon? Intuitively, this is not the case because we know that

different types of vegetation (e.g., hammock vs. turf) and how they are managed will sequester different quantities of CO₂. Using representative 400 m² plot measurements (Zhao et al. 2010) and modeling of tree carbon sequestration (Escobedo et al., 2009) and estimates of lawn sequestration from various land use types in Florida, including their maintenance emissions, we calculated the source/sink potential of a 4 hectare (9.88 acres) site. Only above-ground vegetation values were calculated; soils and below ground organic matter were not included in the calculations.

The take home message is that highly maintained lawns and trees sequester much less CO₂ than more natural areas with little maintenance (Table 1). With more lawn cover than tree canopy cover, the balance can actually shift to emitting CO₂ (e.g., older residential areas in Miami-Dade). Of note is that we did not calculate the impact of built surfaces, just vegetative. The calculations were simplified as we did not add the carbon cost of making and maintaining the power equipment or the carbon cost of growing and transporting sod. In particular, we did not calculate the emission of nitrous oxide (N₂O) from fertilization applications. Urban turfgrass typically emits N₂O after fertilization and/or irrigation. N₂O has a much worse global warming potential (GWP) as its heat-absorbing potential is approximately 300 times more than CO₂. With these unmeasured factors, city parks with high maintenance regimes may have much

larger impacts than reported here. Thus, urban open space that has a large amount of mowed, irrigated, fertilized lawns and pruned shrubs and trees can be a source of CO₂ rather than a sink. These CO₂ emissions are not trivial; for example, a 4-hectare greenspace in Miami-Dade with 85% of the land covered in lawn would emit over 11 tons of CO₂ per year (Table 1).

Further, because below-ground soil carbon sequestration was not calculated, full carbon credit could not be assessed and these above-ground numbers reported should be regarded as a first look at the potential carbon value of urban greenspace. At this stage, natural greenspaces in and around urban areas, with little to no maintenance, seem to be the best option for CO₂ sequestration. Natural urban greenspaces also have other benefits, such as biodiversity conservation, reduced stormwater runoff, and reduced fertilizer applications. Overall, the conservation of urban open space could play a role in reducing Florida's carbon footprint, but highly maintained urban greenspace could be regarded as a source of greenhouse gases. In relation to HB 697, these results indicate that if municipalities and developers are to use green spaces as CO₂ sinks, they will have to justify the creation of such high-maintenance parks and may have to mitigate their effects.
