An Asian Citrus Psyllid Parasitoid *Tamarixia radiata* (Waterston) (Insecta: Hymenoptera: Eulophidae)\(^1\)

Rajinder S. Mann and Lukasz L. Stelinski\(^2\)

**Introduction**

*Tamarixia radiata* (Waterston) (Hymenoptera: Eulophidae) is an effective ectoparasitoid of the *Asian citrus psyllid*, *Diaphorina citri* Kuwayama (Hemiptera: Psyllidae). *Diaphorina citri* is one of the most serious pests of citrus worldwide because it vectors the bacterial pathogen causing huanglongbing (HLB) disease in citrus. In addition, both nymphs and adults are obligate phloem feeders that cause chlorosis on infested leaves and excrete honeydew that promotes the growth of sooty mold. HLB affects plant phloem, causing yellow shoots, mottling, chlorosis, and twig die back which cause rapid tree decline and may ultimately cause tree death. Fruit on diseased trees do not color properly, and can be bitter tasting and misshapen as well as reduced in size (Capoor 1963, Halbert and Manjunath 2004, Bové 2006).

In the United States, *Diaphorina citri* was first discovered in Palm Beach County, Florida on orange jasmine, *Murraya paniculata* (L.) Jack. (Rutaceae) in 1998 (Halbert 1998). It is now a serious pest of citrus in Florida (Michaud 2002, Halbert and Manjunath 2004), and specimens have been found throughout the US, including Florida, Texas, Hawaii, Louisiana, Alabama, Georgia, Mississippi, South Carolina, and California (National Invasive Species Information Center).

Currently all possible vector and disease control methods are being employed to manage HLB in Florida including biological control with *Tamarixia radiata* (Waterston) (Hymenoptera: Eulophidae) and *Diaphorencyrtus aligarhensis* (Shafee, Alam and Agarwal) (Hymenoptera: Encyrtidae) (Hoy et al., 2006, Qureshi et al., 2009). *Tamarixia radiata* is presumed superior to *Diaphorencyrtus aligarhensis* based on previous reports of high psyllid parasitization rates and rapid establishment in new areas (Aubert 1987, Skelly and Hoy 2004). Release of *Tamarixia radiata* revived the citrus industry in Reunion Island after its introduction from India in 1978 (Etienne et al., 2001) and the parasitoid caused substantial decline in *Diaphorina citri* populations in Guadeloupe Island within one year of release (Aubert and Quilici 1984, Etienne et al., 2001).

**Distribution**

*Tamarixia radiata* was discovered in the area of northwestern India (Punjab) which is now within present-day Pakistan (Waterston 1922). Because of the reported high parasitism efficiency and establishment rate of *Tamarixia radiata*, the parasitoid was imported into several countries, including the United States, to control *Diaphorina citri*.

Currently, the parasitoid is found in Brazil, China, Guadeloupe, Indonesia, Mauritius, Mexico, Pakistan, Philippines, Nepal, Taiwan, Vietnam, Puerto Rico, and the United States

An Asian Citrus Psyllid Parasitoid Tamarixia radiata (Waterston) (Insecta: Hymenoptera: Eulophidae)

Description and Life Cycle

Adults

*Tamarixia radiata* adults are small black wasps (0.92 to 1.04 mm long) with widely separated eyes. The adult's head is slightly larger in width than length. The wings are hyaline with pale yellow veins. Sexual dimorphism is marked between the male and female adults. The male antennae are 1.5 times longer than those of females (Onagbola et al., 2009). Males are slightly smaller than females in total length and wing expanse. The female ovipositor is barely protruding (Waterson 1922).

Eggs

The adult female *Tamarixia radiata* lays one or occasionally two eggs beneath a *Diaphorina citri* nymph. Although more than one egg may sometimes be laid beneath a nymph, only one parasitoid larva usually reaches the adult stage and thus *Tamarixia radiata* is regarded as a solitary parasitoid. An adult female *Tamarixia radiata* can deposit up to 300 eggs (Hoy et al., 2006).

Larvae

The newly hatched parasitoid larvae feed on hemolymph from the site of attachment, eventually killing the hosts, *Diaphorina citri* nymphs. The first instar parasitoid larvae are about 0.28 mm long and 0.11 mm wide, while the fourth instar larvae are 1.14 mm long and 0.59 mm wide.

Pupae

Pupation occurs within the mummified *Diaphorina citri* nymphs and new adults emerge through a hole on the thorax or head of the parasitized mummy.

Under experimental conditions (26±1°C, 70% RH), the total developmental period (egg to adult) for the wasps is completed in 11.4 days. The egg, larval, prepupal, and pupal stages are completed in 1.9, 4.0, 0.6 and 4.9 days, respectively.

The average longevity of the female adult (23.6 days) is greater than that of the male (11.4 days). Males are capable of multiple matings. However, mating has no effect on longevity of adults (Chien et al. 1991b). The female to male sex ratio is 1.8 to 3.2, depending upon the origin of the colony and the rearing conditions (Chien 1995, Skelley and Hoy 2004, Hall 2008).
The adult *Tamarixia radiata* parasitoid emerges from the *Diaphorina citri* nymph’s thorax, leaving a round emergence hole visible without magnification. *Tamarixia radiata* females parasitize all immature stages of *Diaphorina citri* and show a significant preference for 5th-instar nymphs (Chien et al., 1991b, Hoy et al., 2006).

In addition to killing nymphs through parasitism, adult females feed on younger nymphs (Chein 1995, Skelley and Hoy 2004). Female *Tamarixia radiata* may obtain protein for egg development by feeding on hemolymph from psyllid nymphs, which is accessed through ovipositor-induced punctures (Hoy et al., 2006). A single *Tamarixia radiata* female is able to kill over 500 psyllids by a combination of host feeding and parasitism. Females also feed on honeydew excreted by psyllids (Hoy et al. 2006). *Tamarixia radiata* adults are strongly attracted to bright fluorescent lights (Skelley and Hoy 2004) and females primarily rely on olfactory cues for host location (Mann et al., 2010).

Currents, the parasitoid is also found in Texas and Puerto Rico where it was not released intentionally. While *Tamarixia radiata* has a short generation time and high reproductive rate in the laboratory, its effectiveness in suppressing psyllid populations under field conditions has been variable in Florida and other adjoining regions (Michaud, 2004, Pluke et al., 2008, Qureshi et al., 2009). Parasitism rates have averaged less than 20% during spring and summer, increasing to 39–56% in the fall as compared to 79 and 88% in Puerto Rico (Pluke et al., 2008). Parasitism rates in Florida are lower than observed in Reunion Island, Guadaloupe, and Puerto Rico.

No hyperparasitoid species attacking *Tamarixia radiata* have yet been observed in the United States (Hall 2008). However, 64–100% mortality of *Tamarixia radiata* has been reported from intraguild predation (killing and eating potential competitors) by coccinellid species in Florida (Michaud 2004, Qureshi et al., 2009). Coccinellids consume parasitized nymphs containing *Tamarixia radiata* larvae thus reducing populations of *Tamarixia radiata*. In addition, the more extreme climatic conditions of Florida and current intense use of insecticides to control *Diaphorina citri* populations are presumed to be responsible for low parasitoid populations in Florida.
